Heavy Metals in the Environment

Im mobilization of Nickel and Other Metals in Contaminated Sediments by Hydroxyapatite Addition

John C. Seaman,* J. Samuel Arey, and Paul M. Bertsch

ABSTRACT

Batch experiments were conducted to evaluate the ability of hydroxyapatite (HA) to reduce the solubility of metals, including the primary contaminants of concern, Ni and U, from contaminated sediments located on the Department of Energy’s Savannah River Site, near Aiken, SC. Hydroxyapatite was added to the sediments at application rates of 0, 5, 15.8, and 50 g kg⁻¹. After equilibrating in either 0.02 M KCl or 0.01 M CaCl₂, the samples were centrifuged and the supernatants filtered prior to metal, dissolved organic C, and PO₄ analyses. The treated soils were then air-dried and changes in solid-phase metal distribution were evaluated using sequential extractions and electron-based microanalysis techniques. Hydroxyapatite was effective at reducing the solubility of U and, to a lesser degree, Ni. Hydroxyapatite was also effective in reducing the solubility of Al, Ba, Cd, Co, Mn, and Pb. Sequential extractions indicate that HA transfers such metals from more chemically labile forms, such as the water-soluble and exchangeable fractions, by altering solid-phase speciation in favor of secondary phosphate precipitates. Hydroxyapatite effectiveness was somewhat reduced in the presence of soluble organics that likely increased contaminant metal solubility through complexation. Arsenic and Cr solubility increased with HA addition, suggesting that the increase in pH and competition from PO₄ reduced sorption of oxyanion contaminants. Energy dispersive x-ray (EDXA) analysis conducted in the transmission electron microscope (TEM) confirmed that HA amendment sequesters U, Ni, Pb, and possibly other contaminant metals in association with secondary Al-phosphates.

IN SITU treatment and stabilization techniques for soils and sediments are typically less expensive and disruptive to functioning, albeit contaminated, ecosystems than conventional excavation, extraction, and disposal procedures. Such techniques enhance the natural attenuation mechanisms controlling contaminant migration, bioavailability, and toxicity, and are based on a fundamental understanding of the natural geochemical processes affecting the speciation and fate of the target contaminant. Previous studies have generally focused on reducing the mobility of a specific contaminant metal, e.g., Pb or U. However, most sites consist of a mixture of various contaminants, often including both inorganic and organic contaminants displaying different chemical properties that impact their mobility and toxicity in the environment (NRC, 1994). The Tims Branch system located on the Department of Energy’s Savannah River Site (SRS) near Aiken, SC, is a prime example, having been contaminated with a variety of metals.

Tims Branch, a second order stream which drains approximately 16 km² within the drainage basin of the Savannah River, was contaminated with uranium (U), nickel (Ni), lead (Pb), chromium (Cr), copper (Cu), thorium (Th), and other metals resulting from nuclear materials production on the SRS (Evans et al., 1992; Pickett, 1990). Significant deposition of contaminants and suspended sediments occurred within Steed Pond, a former farm pond on Tims Branch, due to the longer residence times and reduced flow velocities (Batson, 1994; Batson et al., 1996; Evans et al., 1992). Steed Pond sediments display elevated levels of Ni, U, and several other metals when compared with nonimpacted soils from the southeastern USA (Table 1), with much of the contamination restricted to the upper 45 cm of sediment (Pickett, 1990). The wooden dam ruptured in 1984, draining the pond and exposing the contaminated sediments (Pickett, 1990). Originally it was thought that revegetation would control erosional contaminant transport (Pickett, 1990); however, many of the most contaminated regions of the pond remain unvegetated, suggesting metal toxicity continues to limit plant growth (Batson, 1994). The relatively large affected area, approximately 5.3 ha, and the potential to drastically disturb the Upper Three Runs/Tims Branch stream system and possibly enhance contaminant transport due to erosion during conventional ex situ treatment makes in situ stabilization an attractive remediation alternative.

In situ chemical stabilization techniques typically reduce the mobility of the target contaminant by redirecting chemical speciation in favor of less soluble/labile phases. The addition of apatite minerals [(Ca₅(PO₄)₃X)halide, hydroxyl] has proven effective in stabilizing many transition and heavy metals, metalloids, and radionuclides through the formation of secondary phosphate precipitates that remain stable over a wide range of geochemical conditions (Berti and Cunningham, 1997; Laperche et al., 1997; Ma et al., 1993; Nriagu, 1974; Ruby et al., 1994; Traina and Laperche, 1999; Wright, 1990; Wright et al., 1987). Research into the use of apatite as a soil amendment has focused mainly on Pb remediation. Numerous studies have demonstrated

that apatite addition reduces the solubility, mobility, and bioavailability of Pb in controlled batch studies (Chen et al., 1997b; Ma et al., 1993, 1994a, 1994b; Takeuchi and Arai, 1990; Traina and Laperche, 1999; Wright et al., 1995; Xu and Schwartz, 1994; Xu et al., 1994; Zhang and Ryan, 1998; Zhang et al., 1997) and experiments using Pb-contaminated soils (Chen et al., 1997a, 1997b; Laperche et al., 1997; Ma et al., 1993; Wright et al., 1995).

Apatite addition has been proven effective in reducing the solubility of a wide range of contaminant metals (Arey et al., 1999; Ma et al., 1994b; Wright et al., 1995), which suggests its widespread utility in addressing sites contaminated with multiple metals, such as the high levels of U, Ni and other metals found in Steed Pond (Pickett, 1990). However, the presence of other metals can inhibit contaminant stabilization by reducing the amount and rate at which PO₄ becomes available for precipitation with the target contaminant, and by altering the nature of any secondary phosphate precipitates that are formed (Ma et al., 1994b; Wright et al., 1995). For example, less soluble phases such as strengite (Fe₅PO₄·2H₂O) and variscite (AlPO₄·2H₂O) may control solution-phase phosphate activity under acidic soil conditions (Lindsay, 1979; Nriagu, 1974).

Arey et al. (1999) demonstrated that addition of hydroxyapatite (HA), Ca₅(PO₄)₃OH, reduces U solubility in Steed Pond sediments. However, metal complexation by dissolved organic matter and the buffering capacity of the contaminated material are important factors controlling U solid-phase partitioning. Despite the potential for organic complexation to enhance solubility, HA-treated sediments were greatly undersaturated with respect to U-phosphate precipitates, namely Ca- or K-autunite. Energy dispersive x-ray (EDX) analysis of the treated sediments conducted in a transmission electron microscope (TEM) failed to identify autunite and suggested that U was sequestered primarily in poorly ordered secondary Al/Fe-phosphate phases (Arey et al., 1999).

Clearly the immobilization mechanisms occurring in contaminated soil systems may be far more complex than the simple batch analogs. However, the relatively large land area and shallow nature of the contamination make Steed Pond an ideal site for in situ immobilization techniques. Numerous studies, many of which were cited above, have verified the utility of HA in treating Pb-contaminated soils, and Arey et al. (1999) demonstrated its effectiveness for U. However, little information is available on the effectiveness of apatite in addressing Ni contamination, which can be as high as 5300 mg kg⁻¹ in Steed Pond (Pickett, 1990). Additionally, few studies have evaluated the ability of HA to immobilize a range of contaminant metals in weathered systems where the contaminants have been exposed to the sediments for long time periods. The objective of the present study was to evaluate the effectiveness of HA at chemically stabilizing Ni and other contaminant metals present in Steed Pond sediments that differ in terms of organic C content, and to identify and characterize potential sorptive phases. Two background solutions, 0.02 M KCl or 0.01 M CaCl₂, were used to evaluate the impact of the common ion, i.e., Ca, on HA solubility and contaminant metal partitioning.

**MATERIALS AND METHODS**

Stead Pond sediments are characteristic of the highly weathered soils/sediments of the Atlantic Coastal Plain. The sediments tend to be acidic (pH 4.0–4.5) with the clay fraction dominated by kaolinite with lesser amounts of illite, hydroxy-interlayered vermiculite (HIV), gibbsite, and goethite (Barton, 1994). For the present study, two distinct contaminated strata differing in organic matter content, hereafter referred to as S1 and S2, were collected at depth intervals from 2 to 7 and 7 to 22 cm, respectively, at the same coring site in Steed Pond (Table 2). The samples were stored in a field-moist state at 4°C. Both sediments have similar properties with respect to mineralogy, pH, and texture, but vary greatly with respect to organic C content.

**Batch Equilibrations**

Five g (dry wt.) of field-moist sediment were placed in 50-mL centrifuge tubes with three replicates for each treatment. Four levels of reagent-grade HA were added to each sediment, 0, 0.5, 15.8, and 50 g kg⁻¹, which correspond to 0, 0.5, 1.58, and 5.0% by weight, with 25 mL of 0.02 M KCl or 0.01 M CaCl₂. After equilibrating on a reciprocating shaker for 42 h at 25°C, the sediment suspensions were allowed to settle for at least 2 h before measuring the supernatant pH and electrical conductivity (EC). For comparison, sediment-free centrifuge

tubes were used to evaluate HA dissolution in the two background solutions, 0.02 M KCl or 0.01 M CaCl₂, under pH conditions similar to that of the sediment treatments. Selected treatments were also replicated with batch reaction times of 136 h to determine if equilibrium had been reached with respect to metal immobilization. The suspensions were then centrifuged at 10,000 rpm (11,952 g) for 30 min using a Sorvall RC-2B supercentrifuge and passed through a polycarbonate membrane filter (0.22-μm pore size). A fraction of the filtered supernatant was immediately analyzed for DOC using a Shimadzu TOC-500 organic C analyzer and for soluble orthophosphate using the molybdate ascorbic acid colorimetric method (Olsen and Sommers, 1982). Sulfate (SO₄²⁻), chloride (Cl⁻), and nitrate (NO₃⁻) contents in the same supernatant fraction were determined by ion chromatography (USEPA Method 300.0, 1994). The remaining supernatants were acidified (1% nitric acid) and analyzed for metals by inductively coupled plasma–mass spectrometry (ICP-MS) (Elan 6000, PerkinElmer Corp., Norwalk, CT). The residual-treated soils were air-dried and changes in solid-phase metal distribution were evaluated using sequential extractions and TEM microanalysis techniques.

Toxicity Characteristic Leaching Procedure and Sequential Extraction

A subsample from two of the equilibration replicates of each treatment was extracted using the USEPA standardized Toxicity Characteristic Leaching Procedure (TCLP; USEPA, 1992). The TCLP leaching solution is comprised of 0.1 M glacial acetic acid and 0.0643 M NaOH, with a final pH of 4.93. Fifty g of leaching solution were added to 2.5 g of treated sediment, the mixture was agitated on a reciprocating shaker for 18 h at 25°C, and then centrifuged as described above. After centrifugation, supernatants were filtered through 0.22-μm pore-size polycarbonate filters, acidified to 2% HNO₃, and analyzed for metals using ICP-MS.

Sequential extraction was performed in triplicate for each of the sediment treatments using the modified procedure from Miller et al. (1986), which is more appropriate for highly weathered soils than many of the other commonly used sequential extraction schemes. Each extraction step and the target phase are listed in procedural order from least to most chemically aggressive:

1. Deionized water = Water soluble.
2. 0.5 M Ca(NO₃)₂ = Exchangeable.
3. 0.44 M Glacial acetic acid + 0.1 M Ca(NO₃)₂ = Acid soluble.
4. 0.01 M NH₂OH·HCl + 0.1 M HNO₃ = Mn occluded.
5. 0.1 M Na₂P₂O₇·10H₂O = Organically bound.
6. 0.175 M (NH₄)₂C₂O₄·H₂O, 0.1 M H₂C₂O₄, in the dark = Amorphous Fe oxides.
7. Reduction with 0.5 g Na-dithionite in 0.15 M Na₂H₂C₂O₄ + 0.05 M H₂C₂O₄ (sodium-citrate buffer) = Crystalline Fe oxides.
8. 6 mL of HF and 5 mL of HNO₃ and heated at 880 kPa (120 psi) in a digestion microwave for 30-min intervals until residual digestion was complete = Residual fraction.

Extracted metals in each fraction were quantified by ICP-MS. For comparison with sequential extraction results, total metals for the original unamended soils were determined using a HF/HNO₃-based, microwave-assisted digestion method (USEPA Method 3052) followed by ICP-MS analysis.

Analytical Electron Microscopy

Analytical electron microscopy was used to identify solid phases that may influence contaminant metal solubility. A small fraction of each HA-treated soil and the control samples was embedded in a low viscosity fixative (Embed 812) and cured overnight. The samples were then cut into thin sections (~70 nm) using an ultramicrotome equipped with a diamond knife. The thin sections were then placed onto TEM grids and analyzed using a JEOL 2010 transmission electron microscope (TEM) equipped with a thin-window detector for EDX analysis of lighter elements (Z ≥ 6).

Thermodynamic Modeling

Equilibrium modeling was conducted using the USEPA’s MINTEQA2 Geochemical code (v. 3.11) to compare the batch results with various secondary precipitates that may control metal and PO₄ solubility (USEPA, 1997). The database was updated with the Nuclear Energy Agency’s thermodynamic data set for U minerals (Turner et al., 1993; USEPA, 1997). Solution conditions (i.e., metal and PO₄ concentrations and pH) were based on results from the initial HA/soil equilibria for the 50 g kg⁻¹ amendment treatment level in each of the background equilibrating solutions, 0.01 M CaCl₂ or 0.02 M KCl. The degree of saturation with respect to a specific solid phase (Ω) is defined as

\[ \Omega = \frac{\text{IAP}}{K_{sp}} \]

where IAP is the ion activity product and Ksp is the solubility product. To readily compare the degree of saturation for a set of potential solid phases, the saturation index (SI) is then defined as the log of Ω. If SI < 0 (i.e., negative value), the solution is undersaturated, whereas if SI > 0, the solution is supersaturated with respect to a specified solid phase. If SI = 0, the solution is in equilibrium with a given solid. The saturation indices with respect to HA were determined without including an initial solid phase. To calculate the saturation indices for Ni [Ni(OH)₂, Ni₃(PO₄)₂], Al (varascite), and U (autunite), however, HA was added as an infinite solid without allowing secondary phases to precipitate that would alter the observed solution chemistry.

RESULTS AND DISCUSSION

Steed Pond sediments display elevated levels of U, Ni, Cr, Cu, and Pb that are several times higher than the reported values for nonimpacted soils on the SRS (Pickett, 1990; Pickett et al., 1985; Zeigler et al., 1986). In fact, the levels of U and Ni are several hundred times higher than normal, and apparently limit revegetation in localized areas (Table 1). Hydroxyapatite addition increased Ni and U solubility and increased soluble PO₄ and solution pH (Fig. 1). However, the soluble Ni concentrations in the HA-amended sediments were still >1 mg L⁻¹, much higher than the soluble U concentrations (<50 μg L⁻¹) at the same amendment levels (Arey et al., 1999). In the presence of CaCl₂, the levels of soluble PO₄ for each sediment at a given HA treatment level were consistently less than the KCl treatments, and the soluble Ni and U levels were higher as well. This suggests that HA solubility, available PO₄, and the subsequent impact on contaminant metal immobilization were in part reduced due to the common ion effect of Ca²⁺ on
HA dissolution. However, Ca\(^{2+}\) competition for sorption sites may have also enhanced soluble Ni levels. Soluble PO\(_4\) increased almost linearly as a function of HA addition in sediment-free background solutions (data not shown), and displayed a similar trend in the presence of Steed Pond sediments (Fig. 1C). Soluble PO\(_4\) levels in sediment-free CaCl\(_2\) solution with HA were comparable to those observed in the presence of HA-treated sediments. However, the concentration of soluble PO\(_4\) levels was much higher for the sediment-free KCl solutions, demonstrating the impact of both the sediment components and the background solution (i.e., Ca\(^{2+}\)) in controlling HA dissolution. The increase in soluble PO\(_4\) with treatment level for all the solution and sediment treatments suggests that HA dissolution may have been kinetically limited during the batch experiments. However, the final aqueous phase concentra-

Fig. 2. Aqueous PO\(_4\) as related to (A) DOC concentration, (B) pH, and (C) Ni concentration in hydroxyapatite (HA)-amended sediments.
Fig. 4. Effect of hydroxyapatite (HA) amendment on soluble (A) As and (B) Cr concentration for two sediments equilibrated in 0.02 M KCl or 0.01 M CaCl₂. Bars represent the standard deviation of the treatment means.

Function of PO₄ concentration, dissolved organic carbon (DOC) and suspension pH increased, while soluble Ni decreased with increasing soluble PO₄ (Fig. 2). Each sediment apparently displays a clearly distinct trend with respect to DOC, pH, and Ni as a function of PO₄ levels. Treatments in the CaCl₂ background solution display consistently lower soluble PO₄ for a given HA treatment level, again suggesting that the CaCl₂ solution reduces HA solubility due to the common ion effect. The increased solubilization of organic matter with HA addition may have resulted from PO₄ competition with Cd, Co, and Pb for two sediments equilibrated in 0.02 M KCl or 0.01 M CaCl₂. Bars represent the standard deviation of the treatment means.

Similar levels of soluble Ni were observed for both sediments despite more than twofold differences in total Ni content, i.e., 946 vs. 1922 mg kg⁻¹ (Table 1). Previous studies have clearly demonstrated the role of organics in controlling metal partitioning in Steed Pond sediments (Arey et al., 1999; Batson et al., 1996). As observed for U (Arey et al., 1999), the enhanced metal solubility may reflect the impact of complexation by native soluble humic substances. When the treatments are plotted as a function of PO₄ concentration, dissolved organic carbon (DOC) and suspension pH increased, while soluble Ni decreased with increasing soluble PO₄ (Fig. 2). Each sediment apparently displays a clearly distinct trend with respect to DOC, pH, and Ni as a function of PO₄ levels. Treatments in the CaCl₂ background solution display consistently lower soluble PO₄ for a given HA treatment level, again suggesting that the CaCl₂ solution reduces HA solubility due to the common ion effect. The increased solubilization of organic matter with HA addition may have resulted from PO₄ competition with anionic organic acids and humic substances for sorption sites, the enhanced solubility of humics with increasing pH, or the precipitation of metals with PO₄ that would otherwise act to coagulate soluble organics (Bhatti et al., 1998; Lopez-Hernandez et al., 1986; Violante et al., 1991; Yuan, 1980). At a given soluble PO₄ concentration, however, sediment S1 displayed consistently higher DOC and Ni levels (Fig. 2), indicating that humics enhanced metal solubility by lowering the free-ion activity product for the metal being complexed.
Fig. 5. Transmission electron microscope (TEM) micrographs of (A) fine-grained secondary Al/Fe-phosphate precipitates (40K magnification), (B) fine-grained, lath-shaped residual hydroxyapatite (HA) (50K magnification), and (C) typical energy dispersive x-ray (EDXA) spectrum of Ni- and U-rich secondary Al/Fe-phosphate precipitates in sediment S1 amended with 50 g kg\(^{-1}\) HA.

Demonstrating the potential efficacy of HA in addressing soils/sediments with multiple contaminant metals. In contrast, however, HA noticeably increased the solubility of As, and to a lesser degree Cr (Fig. 4). This is likely due to the increased sorption competition between PO\(_4\) and possibly humics with the oxyanion species of As (arsenate and arsenite) and Cr (James and Bartlett, 1983; Peryea, 1991), demonstrating that HA would not be effective for remediating such oxyanion contaminants.

Mechanistic interpretation of batch equilibration data is somewhat difficult because of the inability to discrimi-
The levels of U were generally lower than those of Ni and Pb, indicating that residual HA may play a role in the precipitation of metal oxyhydroxides due to the buffering effect of HA, with respect to Ni(OH)2 and Ni3(PO4)2. The solutions were undersaturated (i.e., SI < 0) with respect to HA, Ni, and Al mineral phases. Despite the observed presence of residual HA, the solutions were undersaturated with respect to HA (Table 4). The saturation indices for variscite (AlPO4·2H2O), an Al phosphate phase thought to control PO4 activity under acidic soil conditions (Lindsay, 1979; Nriagu, 1974), were close to 0, especially for the S2 sediment that had less dissolved organic matter, which may have enhanced metal solubility for the S1 sediment. In fact, the two saturation values for the S2 sediment are likely to be even more undersaturated with respect to residual HA.

In conclusion, the results of this study suggest that residual HA may play a role in the precipitation of metal oxyhydroxides due to the buffering effect of HA, with respect to Ni(OH)2 and Ni3(PO4)2. The solutions were undersaturated (i.e., SI < 0) with respect to HA, Ni, and Al mineral phases. Despite the observed presence of residual HA, the solutions were undersaturated with respect to HA (Table 4). The saturation indices for variscite (AlPO4·2H2O), an Al phosphate phase thought to control PO4 activity under acidic soil conditions (Lindsay, 1979; Nriagu, 1974), were close to 0, especially for the S2 sediment that had less dissolved organic matter, which may have enhanced metal solubility for the S1 sediment. In fact, the two saturation values for the S2 sediment are likely to be even more undersaturated with respect to residual HA.

**Thermodynamic Modeling**

MinteqA2 model input parameters were based on the 50 g kg⁻¹ HA treatment level because residual HA was observed during TEM analysis for both materials at this treatment level (Table 3). The degree of saturation with respect to residual HA was based solely on the solution composition. However, HA was entered as an infinite solid for computing the degree of saturation with respect to Ni, U, and Al mineral phases. Despite the observed presence of residual HA, the solutions were undersaturated with respect to HA (Table 4). The saturation indices for variscite (AlPO4·2H2O), an Al phosphate phase thought to control PO4 activity under acidic soil conditions (Lindsay, 1979; Nriagu, 1974), were close to 0, especially for the S2 sediment that had less dissolved organic matter, which may have enhanced metal solubility for the S1 sediment. In fact, the two saturation values for the S2 sediment are likely to be even more undersaturated with respect to residual HA.

In conclusion, the results of this study suggest that residual HA may play a role in the precipitation of metal oxyhydroxides due to the buffering effect of HA, with respect to Ni(OH)2 and Ni3(PO4)2. The solutions were undersaturated (i.e., SI < 0) with respect to HA, Ni, and Al mineral phases. Despite the observed presence of residual HA, the solutions were undersaturated with respect to HA (Table 4). The saturation indices for variscite (AlPO4·2H2O), an Al phosphate phase thought to control PO4 activity under acidic soil conditions (Lindsay, 1979; Nriagu, 1974), were close to 0, especially for the S2 sediment that had less dissolved organic matter, which may have enhanced metal solubility for the S1 sediment. In fact, the two saturation values for the S2 sediment are likely to be even more undersaturated with respect to residual HA.

**Electron Microscopy**

As observed by Arey et al. (1999) for U in unamended Steed Pond sediments, Ni appeared to be widely dispersed without the presence of an obvious enriched sorptive phase. Secondary Al/Fe phosphates, nanocrystalline in nature and containing only trace amounts of residual Ca²⁺, were observed in the HA-treated sediments (Fig. 5). A portion of the Fe detected by EDXA was identified by electron diffraction as goethite crystals, which were often closely associated with the poorly ordered phosphate precipitates, making it difficult to differentiate Fe associated with the secondary precipitate. Phosphate and metals sorbed to goethite can act as a precursor for secondary phosphate precipitation below the solubility threshold for a given phase (Sato et al., 1997), i.e., surface facilitated precipitation. Uranium, Ni, and in some cases Pb were associated with the secondary Al/Fe–PO4 precipitates (Fig. 5C). In contrast, residual HA grains in the treated sediments contained an appropriate Ca/P ratio, and were much larger and more crystalline than the secondary precipitates, with little or no detectable U, Ni, or Pb (Fig. 5B).

## Table 3. MinteqA2 input parameters based on the batch equilibration data for sediment S1 and S2 amended with 50 g kg⁻¹ HA in either a 0.01 M CaCl₂ or 0.02 M KCl background solution.

phase transfer is far more sensitive to pH and other solution conditions than the rapid precipitation of an aqueous-phase metal when exposed to HA (Zhang et al., 1997). High levels of soluble native metals commonly encountered in soil systems, such as Al in the present study, or contaminant metals such as Cu, can effectively reduce Pb precipitation and pyromorphite formation, although the level of inhibition may not necessarily coincide with precipitation of the confounding metals (Ma et al., 1994b). In studies of binary metal systems (i.e., Al and Pb, Cu and Pb, etc.), pyromorphite formation was inhibited despite sufficient Pb precipitation. Alternate secondary crystalline Fe(II) and Al phases were not evident from XRD, which suggests the formation of poorly crystalline, mixed metal phosphates (Ma et al., 1994b). The transfer of Ni and U to poorly ordered secondary Al/Fe-phosphate phases in the current study is similar to the observations of Ma et al. (1994a, 1994b) for Pb precipitation in binary metal systems. In this case, however, the solubility of the resulting phase is less than that of the idealized phosphate precipitate for Ni or U (Areý et al., 1999).

Toxicity Characteristic Leaching Procedure and Sequential Extractions

Less U, Al, Pb, and Cd were extracted by TCLP with increasing HA addition (data not shown). However, the results for Ni extraction were extremely variable without a clear discernable trend as a function of amendment level (Fig. 6). A significant portion of the total Ni, and certainly a much higher fraction of the readily labile Ni (soluble, exchangeable, etc.), was extracted from the control and lower HA treatment levels during the initial batch equilibrations, leaving less Ni present for the subsequent extraction by TCLP or the sequential extractants. To account for such a bias, the amount of Ni removed during the initial equilibration was added to the TCLP data. After the correction, a clear trend of decreasing Ni extraction with increasing HA treatment level becomes apparent (Fig. 6). Although this approach seems reasonable, it overestimates the effectiveness of HA since the sum of TCLP-extractable Ni and soluble Ni in soils equilibrated without HA is considerably greater than TCLP extractable Ni for materials that had not been subjected to the initial equilibration experiment. Increased Ni solubility due to the physical agitation associated with the initial 42-h equilibration step may account for such a discrepancy.

The average mass recovery for Ni in sequential extractions was 91.4% (± 4.8%) when Ni removed in the initial batch equilibration was included. As might be expected, the same trends with respect to HA addition observed during the initial equilibrations were repeated in the water-soluble extraction data, despite the bias against the nonamended sediment resulting from metal extraction during the initial equilibration step. Hydroxyapatite was effective in reducing water-soluble Al, Ba, Cd, Co, Mn, Ni, Pb, and U for both sediments, but As increased in the water-soluble fraction with HA addition.

In general, a transfer from the water-soluble, exchangeable, and dilute acid-soluble fractions to the Mn-occluded fraction was observed for most of the metals for which HA was most effective, i.e., Al, Pb, and U. Trends with respect to other metals were less conclusive, likely due to the lower amounts of those metals present
in the sediments. Exchangeable and dilute acid-soluble Ni increased somewhat with HA addition, but to a lesser degree than observed for the Mn-occluded fraction (Fig. 7). As discussed above for TCLP, the results for the water-soluble, exchangeable, and possibly even more resistant fractions have been somewhat biased against the positive influence of HA (i.e., reduction in metal extractability with increasing HA) by the initial batch equilibrations. Metal partitioning to the Mn-occluded fraction is consistent with the previous observations of Arey et al. (1999) with respect to U in these sediments and demonstrates the operational nature of such extraction methods. In fact, the sediments in question have only minor amounts of Mn oxides, and more U and Ni compared with Mn was extracted during the Mn-occluded extraction procedure. This suggests that HA transfers such metals to secondary phosphate precipitates, which were more readily solubilized at the lower pH of the Mn-occluded extract (pH = 1.26) compared to the acid soluble extract (0.44 M glacial acetic acid, pH = 2.55).

**SUMMARY AND CONCLUSIONS**

Hydroxyapatite addition lowered the solubility of several contaminant and native soil metals in two highly weathered containment pond sediments, demonstrating the utility of HA for remediating a wide range of metal-contaminated sites. However, HA was less effective in reducing the solubility and lability of Ni compared with U (Arey et al., 1999), the two primary contaminants of concern in Steed Pond. Even at high HA treatment levels, soluble Ni in the batch equilibrations exceeded 1 mg L$^{-1}$. The moderate effectiveness of HA with respect to Ni compared to U, suggests that such a treatment may be a means of reducing plant uptake of U and increasing survival in a phytoextraction scheme targeting Ni so that the Ni-enriched plant materials are not considered a mixed waste, i.e., metals and radionuclides.

A comparison of similar sediments that differ in organic matter content suggests that complexation by DOC increases solubility of complexed metals such as Ni and U. Initial batch data and micro-analysis of the treated soils suggests that metals such as U, Ni, Al, and Pb are transferred from readily labile fractions, such as the water-soluble and exchangeable fractions, to more resistant secondary phosphates that were solubilized by the Mn-occluded extract due to the acidic pH of the extractant solution. The difference in particle size, morphology, and degree of crystallinity observed for contaminant-rich Al-phosphate precipitates compared with the residual HA support the formation of secondary precipitates rather than metal sorption by weathered HA grains. Although elevated levels of Ni were clearly associated with the secondary Al-phosphate precipitates, subsequent extraction results suggest that the degree/strength of Ni sorption with such phases is much less than observed for U, Al, and Pb.

**ACKNOWLEDGMENTS**

This research was supported by Financial Assistance Award no. DE-FC09-96SR18546 from the DOE to the University of Georgia Research Foundation. J.S. Arey’s participation was funded by the National Science Foundation under Grant no. 9732138. The authors would like to acknowledge the thoughtful comments of Dr. C. Strojan and Dr. B. Jackson on an early version of the manuscript and the assistance of Dr. L. Keller (MVA, Norcross, GA) with the electron microscopy.
